

# Expressions Have Types

 [coursera.org/learn/programming-fundamentals/supplement/SCzBA/expressions-have-types](https://coursera.org/learn/programming-fundamentals/supplement/SCzBA/expressions-have-types)

In the Expressions lesson, we learned that expressions are evaluated to values—if you have  $a+b*2$ , the current value of  $b$  is read out of its box, multiplied by 2, then the value of  $a$  is read out of its box, and added to the product of  $b*2$ . The expression evaluates to the resulting sum.

Expressions also have types, which are determined by the types of the sub-expressions that make them up. The simplest expressions are constants, which have type `int` if they are integer constants (e.g., 2 or 46), or type `double` if they are real constants (e.g., 3.14, or -8.19). The types of constants can be modified by applying a letter suffix if needed (U for unsigned, L for long, and f for float): 3.14f is a constant with type float, and 999999999999L is a constant with type long int. The next simplest type of expression is a variable, which has whatever type it was declared to have.

Most (but not all) expressions with binary operators— $e1 \text{ op } e2$  (e.g.,  $a + b$  or  $c * 4$ )—have the same type as their operands. If  $a$  and  $b$  are doubles, then  $a + b$  is a double as well. Likewise, if  $c$  is an int, then  $c * 4$  is also an int (note that 4 is an int).

The type of a function is its declared return type. That is, if you have

1

2

```
int f (int x, int y) { ... }  
int g (double d, char c) { ... }
```

then the expression  **$f(3, 4) + g(42.6, 'a')$**  has type `int`. We can see this from the fact that  **$f(3, 4)$**  has type `int` ( $f$  is declared to return an int), as does  **$g(42.6, 'a')$** . As we just discussed, adding two ints results in an int.
